# LINEAR REGRESSION

Buckle up...

### Data Matrix

*N* the number of samples

p the number of features  $X \in \mathbb{R}^{N \times p}$ 

$$\mathbf{X} = \begin{pmatrix} x_{00} & \cdots & x_{0p} \\ \vdots & \ddots & \vdots \\ x_{N0} & \cdots & x_{Np} \end{pmatrix}$$

#### Linear Model

We want to find some linear function which takes a single observation

$$X^T = (X_0, X_1, \dots, X_p)$$

and makes a prediction using a function of the form

$$f(X) = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_p X_p$$

$$f(X) = \beta_0 + \sum_{j=1}^{p} X_j \beta_j$$

### Linear Model

This can be written as a vector product:

$$f(X) = \beta_0 + \sum_{j=1}^{p} X_j \beta_j$$

is the same as

$$f(X) = \beta_0 + X^T \cdot \beta$$

We wish to minimize the residual sum of squares:

$$RSS = \sum_{i=1}^{N} (y_i - f(x_i))^2$$

$$RSS = \sum_{i=1}^{N} \left( y_i - \beta_0 - \sum_{j=1}^{p} X_j \beta_j \right)^2$$

Why do we choose to minimize this?

- 1. This is a reasonable measure of distance:
  - The quantity  $(y_i f(x_i))^2$  is always positive, as required for a metric
  - The distance from the set of true observations might as well be the sum of all the distances (ie. the distance from each prediction to the true observation, summed)
- 2. If we assume that our experimental errors are Gaussian then minimizing the RSS is equivalent to finding the most likely model under this assumption.
  - We will discuss this more later

How to find the least-squares solution?

Write the RSS as a matrix-vector equation:

$$RSS = \sum_{i=1}^{N} \left( y_i - \beta_0 - \sum_{j=1}^{p} x_{ij} \beta_j \right)^2$$

$$RSS = (\mathbf{y} - \mathbf{X}\beta)^T (\mathbf{y} - \mathbf{X}\beta)$$

To minimize RSS, take the usual approach of minimization:

$$\frac{\partial RSS}{\partial \beta} = \frac{\partial \{(\mathbf{y} - \mathbf{X}\beta)^T (\mathbf{y} - \mathbf{X}\beta)\}}{\partial \beta}$$

$$0 = -2 \mathbf{X}^T (\mathbf{y} - \mathbf{X}\beta)$$

$$0 = \mathbf{X}^T \mathbf{y} - \mathbf{X}^T \mathbf{X}\beta$$

$$\mathbf{X}^T \mathbf{X}\beta = \mathbf{X}^T \mathbf{y}$$

$$\hat{\beta} = (X^T X)^{-1} X^T y$$

$$\hat{y} = X \hat{\beta} = X (X^T X)^{-1} X^T y$$

#### Some Matrix Rules

$$(\mathbf{A}\mathbf{B})^{T} = \mathbf{B}^{T}\mathbf{A}^{T}$$

$$\frac{\partial \mathbf{x}^{T}\mathbf{a}}{\partial \mathbf{x}} = \frac{\partial \mathbf{a}^{T}\mathbf{x}}{\partial \mathbf{x}} = \mathbf{a}$$

$$\frac{\partial \mathbf{a}^{T}\mathbf{X}\mathbf{b}}{\partial \mathbf{X}} = \mathbf{a}\mathbf{b}^{T}$$

$$\frac{\partial \mathbf{a}^{T}\mathbf{X}^{T}\mathbf{b}}{\partial \mathbf{X}} = \mathbf{b}\mathbf{a}^{T}$$

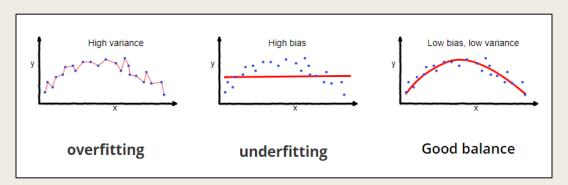

$$\frac{\partial \mathbf{a}^{T}\mathbf{X}^{T}\mathbf{b}}{\partial \mathbf{X}} = \frac{\partial \mathbf{a}^{T}\mathbf{X}^{T}\mathbf{a}}{\partial \mathbf{X}} = \mathbf{a}\mathbf{a}^{T}$$

$$\frac{\partial \mathbf{b}^{T}\mathbf{X}^{T}\mathbf{X}\mathbf{c}}{\partial \mathbf{X}} = \mathbf{X}(\mathbf{b}\mathbf{c}^{T} + \mathbf{c}\mathbf{b}^{T})$$

$$\frac{\partial}{\partial \mathbf{A}}(\mathbf{x} - \mathbf{A}\mathbf{s})^{T}\mathbf{W}(\mathbf{x} - \mathbf{A}\mathbf{s}) \stackrel{\mathbf{T}}{=} -2\mathbf{W}(\mathbf{x} - \mathbf{A}\mathbf{s})\mathbf{s}^{T}$$

#### Comments on least squares:

- The least squares solution is unique only if X is of full rank (all columns linearly independent)
- Gauss-Markov theorem: the least squares estimate is the minimum variance estimate amongst all unbiased linear estimates

- Least squares solutions often have low variance but high bias
- It can be difficult to interpret which terms in the model are most important

- When there are many correlated variables in a linear regression problem then the coefficients can be highly variable
  - The reason for this is that huge coefficients are balanced by equally small coefficients on correlated variables
- Solution: add a penalty for large coefficients

$$\hat{\beta}_{ridge} = argmin_{\beta} \left\{ RSS + \lambda \sum_{j=1}^{p} \beta_{j}^{2} \right\}$$

■ Now the criterion for the solutions is to minimize  $\Omega(\lambda)$ :

$$\Omega(\lambda) = (\mathbf{y} - \mathbf{X}\beta)^{T}(\mathbf{y} - \mathbf{X}\beta) + \lambda \beta^{T}\beta 
\frac{\partial \Omega}{\partial \beta} = \frac{\partial \{(\mathbf{y} - \mathbf{X}\beta)^{T}(\mathbf{y} - \mathbf{X}\beta)\}}{\partial \beta} + \frac{\partial (\lambda \beta^{T}\beta)}{\partial \beta} 
0 = -2 \mathbf{X}^{T}(\mathbf{y} - \mathbf{X}\beta) + 2\lambda\beta 
(\mathbf{X}^{T}\mathbf{X} + \lambda \mathbf{I})\beta = \mathbf{X}^{T}\mathbf{y}$$

$$\hat{\beta} = (X^T X + \lambda I)^{-1} X^T y$$

$$\hat{y} = X \hat{\beta} = X (X^T X + \lambda I)^{-1} X^T y$$

Another way to understand why this works is to looks at the SVD of the solution:

Recall that the SVD of a matrix is:

$$X = UDV^T$$

with the properties that D is a diagonal matrix and  $U^TU = I$ ,  $VV^T = I$ 

$$\hat{\mathbf{y}} = \mathbf{X}\hat{\boldsymbol{\beta}} = \mathbf{X}(\mathbf{X}^{T}\mathbf{X} + \lambda \mathbf{I})^{-1}\mathbf{X}^{T}\mathbf{y}$$

$$\mathbf{X}\hat{\boldsymbol{\beta}} = \mathbf{U}\mathbf{D}\mathbf{V}^{T}(\mathbf{V}\mathbf{D}^{T}\mathbf{U}^{T}\mathbf{U}\mathbf{D}\mathbf{V}^{T} + \lambda \mathbf{I})^{-1}\mathbf{V}\mathbf{D}^{T}\mathbf{U}^{T}\mathbf{y}$$

$$\mathbf{X}\hat{\boldsymbol{\beta}} = \mathbf{U}\mathbf{D}\mathbf{V}^{T}(\mathbf{D}^{2} + \lambda \mathbf{I})^{-1}\mathbf{V}\mathbf{D}^{T}\mathbf{U}^{T}\mathbf{y}$$

$$\mathbf{X}\hat{\boldsymbol{\beta}} = \mathbf{U}\mathbf{D}(\mathbf{D}^{2} + \lambda \mathbf{I})^{-1}\mathbf{V}^{T}\mathbf{V}\mathbf{D}^{T}\mathbf{U}^{T}\mathbf{y}$$

$$\mathbf{X}\hat{\boldsymbol{\beta}} = \mathbf{U}\mathbf{D}(\mathbf{D}^{2} + \lambda \mathbf{I})^{-1}\mathbf{D}\mathbf{U}^{T}\mathbf{y}$$

$$X\hat{\beta} = \sum_{j=1}^{p} \mathbf{u}_{j} \frac{d_{j}^{2}}{d_{j}^{2} + \lambda} \mathbf{u}_{j}^{T} \mathbf{y}$$

■ Compare this to the least squares decomposition:

Ridge regression 
$$X \hat{\beta}_{ridge} = \sum_{j=1}^p \boldsymbol{u}_j \frac{d_j^2}{d_j^2 + \lambda} \boldsymbol{u}_j^T \boldsymbol{y}$$
 Least squares regression 
$$X \hat{\beta}_{LS} = \boldsymbol{U} \boldsymbol{U}^T \boldsymbol{y} = \sum_{j=1}^p \boldsymbol{u}_j \boldsymbol{u}_j^T \boldsymbol{y}$$

- lacktriangle So we see that ridge regression shrinks the coefficients in the basis of  $oldsymbol{U}$
- Recall from PCA theory that this basis is related to components of maximum variance, and it appears  $\lambda$  shrinks components with small variance fastest
- Ridge regression is also known as  $\mathbb{L}_2$  regularization, Tikhonov regularization, or weight-decay in training neural nets

#### The Lasso

- Also known as  $\mathbb{L}_1$  regularization or basis pursuit
- The goal is the same as in ridge regression, but the penalty is different. Now we write the objective as

$$\hat{\beta}_{ridge} = argmin_{\beta} \left\{ \sum_{i=1}^{N} \left( y_i - \beta_0 - \sum_{j=1}^{p} x_{ij} \beta_j \right)^2 \right\}, \text{ subject to } \sum_{j=1}^{p} |\beta_j| \le t$$

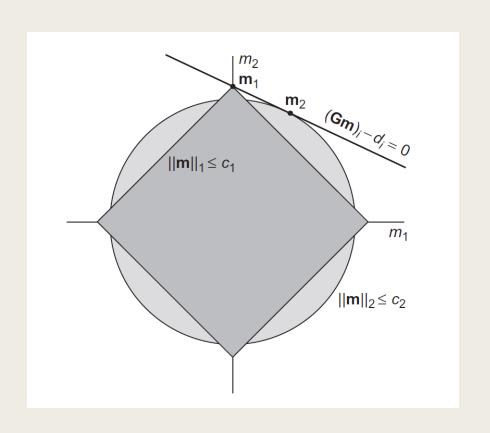

This can also be written in *Lagrangian form*:

$$\hat{\beta}_{ridge} = argmin_{\beta} \left\{ \frac{1}{2}RSS + \lambda \sum_{j=1}^{p} |\beta_{j}| \right\}$$

#### The Lasso

- The Lasso is non-linear in y so there is no closed-form solution. The optimal choice of  $\beta$  is found by iterative optimization procedures
- The advantage of the Lasso is that some coefficients can actually be set to 0 by the optimization procedure (as opposed to ridge regression, which only sends them to small values). This gives a clear interpretation of which terms are important.

# Visualization of $\mathbb{L}_2$ vs $\mathbb{L}_1$ regularization

# Regression using derived inputs

There are some methods of pre-processing our data which can achieve similar effects in reducing the model terms:

■ PCA: we can find a regression along principle components instead of the original axes the data was given in.

Compute the SVD  $\pmb{X} = \pmb{U} \pmb{D} \pmb{V}^T$  and define  $\pmb{Z} = \pmb{U} \widetilde{\pmb{D}}$  for  $\widetilde{\pmb{D}} \in \mathbb{R}^{N \times M}$  , M < p .

Now find the least squares solution  $\beta$  for  $y = Z\beta^T$ 

■ Partial least squares (PLS): similar to PCA in that we construct new components and perform the regression in a truncated version of this space.

Compute  $\phi_{1j} = \langle x_j, y \rangle$  for each  $j \in \{1, ... p\}$ 

Construct the derived input  $\mathbf{z}_1 = \sum_j \phi_{1j} \mathbf{x}_j$ 

Compute the coefficient  $\hat{\theta}_1 = \langle \mathbf{z}_1, \mathbf{y} \rangle / \langle \mathbf{z}_1, \mathbf{z}_1 \rangle$ 

Orthogonalize the remaining  $x_{i+1}, x_{i+2}, ...$  with respect to  $z_1$ 

Repeat the above procedure for all  $\phi_{m,j}$  and  $x_j$  that are left

### Linear Methods of Classification

#### **Linear Discriminant Analysis**

Suppose we have a set of classes  $G = \{1, 2, ... k, ... K\}$  and we wish to compute the probability that observation X = x is in class G = k. This can be written using Bayes theorem as:

$$P(G = k | X = x) = \frac{P_k(x)P_G(k)}{\sum_{j=1}^{K} P_j(x)P_G(j)}$$

We assert that all classes are distributed as multivariate Gaussians of the form

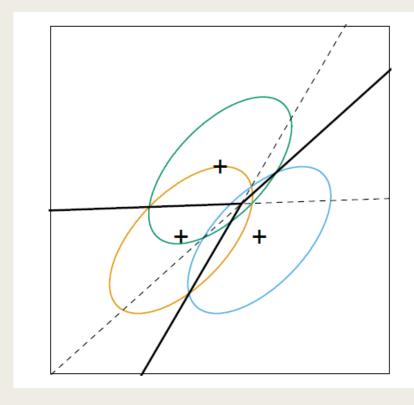

$$P_j(x) = \frac{1}{(2\pi)^{p/2} |\mathbf{\Sigma}_k|^{1/2}} e^{-\frac{1}{2}(x - \mu_k)^T \mathbf{\Sigma}_k^{-1} (x - \mu_k)}$$

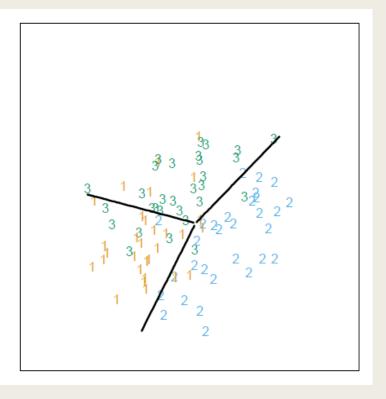

If we assume  $\Sigma_k$  are equal for all k then we can compare the log-ratio of probabilities:

$$\log \frac{P(G=k|X=x)}{P(G=l|X=x)} = \log \frac{P_G(k)}{P_G(l)} + \log \frac{P_k(x)}{P_l(x)}$$

### Linear Methods of Classification

#### **Linear Discriminant Analysis**

We wish to model posterior log-probabilities of classes using linear functions in x, subject to the constraint that these functions sum to 1 and remain in [0,1]

$$\log \frac{\Pr(G = 1 | X = x)}{\Pr(G = K | X = x)} = \beta_{10} + \beta_1^T x$$

$$\log \frac{\Pr(G = 2 | X = x)}{\Pr(G = K | X = x)} = \beta_{20} + \beta_2^T x$$

$$\vdots$$

$$\log \frac{\Pr(G = K - 1 | X = x)}{\Pr(G = K | X = x)} = \beta_{(K-1)0} + \beta_{K-1}^T x.$$

■ The consequence of this formulation is that

$$\Pr(G = k | X = x) = \frac{\exp(\beta_{k0} + \beta_k^T x)}{1 + \sum_{\ell=1}^{K-1} \exp(\beta_{\ell0} + \beta_\ell^T x)},$$

$$\Pr(G = K | X = x) = \frac{1}{1 + \sum_{\ell=1}^{K-1} \exp(\beta_{\ell0} + \beta_\ell^T x)},$$

Quick Derivation for 2 classes:

$$\log \frac{P(G=1|X=x)}{P(G=2|X=x)} = \beta_{10} + \beta_{11}x$$

$$e^{\beta_{10} + \beta_{11}x} = \frac{P(G=1|X=x)}{P(G=2|X=x)} = \frac{P(G=1|X=x)}{1 - P(G=1|X=x)}$$

$$P(G=1|X=x) = \frac{e^{\beta_{10} + \beta_{11}x}}{1 + e^{\beta_{10} + \beta_{11}x}}$$

■ Consider the two-class example. Use an indicator function to code the classes:

$$y_i = \begin{cases} 1 & \text{if } x_i \text{ is in class } 1\\ 0 & \text{if } x_i \text{ is in class } 2 \end{cases}$$

We can write the log-likelihood of a set of N observations as a function of the parameters  $\beta = \{\beta_{10}, \ \beta_1\}$ 

$$\ell(\beta) = \sum_{i}^{N} \log p_{k}(x_{i}; \beta) = \sum_{i=1}^{N} \{y_{i} \log p(x_{i}; \beta) + (1 - y_{i}) \log(1 - p(x_{i}; \beta))\}$$

$$\ell(\beta) = \sum_{i=1}^{N} \{y_{i} \beta^{T} x_{i} - \log(1 + e^{\beta^{T} x_{i}})\}$$

 $\blacksquare$  Find the maximum likelihood estimate of  $\beta$  by taking the derivative

$$\frac{\partial \ell(\beta)}{\partial \beta} = 0 = \sum_{i=1}^{N} x_i (y_i - p(x_i; \beta))$$

lacktriangle Typically this set of p equations for eta is solved using the Newton-Raphson method

$$\beta^{new} = \beta^{old} - \left(\frac{\partial^2 \ell(\beta)}{\partial \beta \partial \beta^T}\right)^{-1} \frac{\partial \ell(\beta)}{\partial \beta}$$

If we define W a  $N \times N$  diagonal matrix such that  $w_{ii} = p(x_i; \beta^{old})(1 - p(x_i; \beta^{old}))$  then the Newton-Raphson step becomes

$$\beta^{new} = (\mathbf{X}^T \mathbf{W} \mathbf{X})^{-1} \mathbf{X}^T \mathbf{W} (\mathbf{X} \beta^{old} + \mathbf{W}^{-1} (\mathbf{y} - \mathbf{p}))$$

Note: this is also known as the iteratively reweighted least squares (IRLS) algorithm

### That's all!

■ For more details, I recommend *The Elements of Statistical Learning* by Hastie, Tibshirani, and Friedman
